Abstract

This study examines the role of nutrition in predicting COVID-19 outcomes, focusing on the mortality and recovery rates across global populations. Using the "COVID-19 Healthy Diet Dataset," dietary metrics such as caloric, protein, and fat intake were analyzed to determine their impact on pandemic resilience, specifically COVID-related deaths. The project involved cleaning and transforming raw data, performing exploratory data analysis (EDA), and applying machine learning tools including Ordinary Least Squares Regression, Support Vector Machine and Random Forest. Results demonstrated that higher protein and fat intake exhibited significantly higher mortality risks. These findings highlight the importance of integrating nutritional considerations into public health strategies and diets to improve resilience during pandemics and other health crises.

Introduction

The COVID-19 pandemic has exposed stark disparities in health outcomes across countries, prompting efforts to understand the factors driving these differences. While healthcare infrastructure and socioeconomic conditions have been extensively studied, the role of nutrition has not been adequately explored. Nutrition significantly impacts immune function, inflammation, and recovery from illnesses, making it a potentially critical factor in explaining variations in COVID-19 outcomes (Calder et al., 2020). This study examines whether dietary metrics such as caloric, protein, and fat intake can predict COVID-19 outcomes, specifically mortality and recovery rates. By investigating these relationships, this research seeks to provide actionable insights for public health policies and strategies to enhance resilience during future pandemics. The central question guiding this analysis is whether global disparities in dietary supply influence the health outcomes of populations affected by COVID-19 and if so, how these insights can inform targeted interventions.

Data Description

The dataset used in this study, the "COVID-19 Healthy Diet Dataset," was obtained from Kaggle and includes detailed information on dietary supply metrics and COVID-19 statistics for various countries (Mariaren, 2020). The dietary metrics include caloric, protein, and fat intake per capita, while the COVID-19 data include case counts, deaths, and recoveries. The dataset is split into caloric, food, protein, and fat intake which was all merged together to be preprocessed. Additionally, demographic variables such as healthcare access and economic indicators provide contextual information. Despite its richness, the dataset required extensive cleaning and preprocessing due to challenges such as missing values, outliers, and inconsistent scaling. Missing values were particularly prevalent in the dietary metrics for some regions, where outliers

in both dietary and COVID-19 statistics threatened to distort the analyses. These issues necessitated the implementation of robust preprocessing techniques to ensure the integrity of the analysis and model results.

The distribution of deaths is right-skewed with many countries' mortality rate under 5%. The figure below illustrates the mortality of COVID-related deaths:

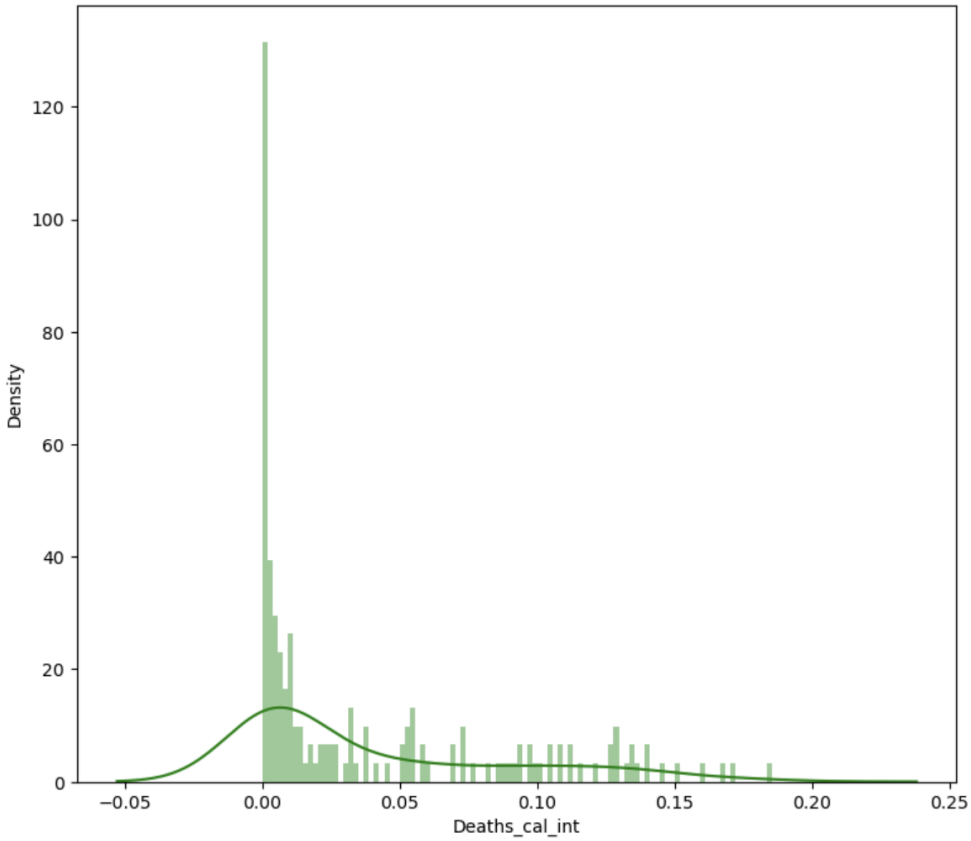

Figure 1. Density curve of mortality of COVID-related deaths

Exploratory Data Analysis

Exploratory data analysis (EDA) provided significant insights into the relationships between dietary metrics and COVID-19 outcomes. Such correlations are essential for identifying potential predictive variables and understanding their influence on target outcomes, as discussed by Tan et al. (2019). Additionally, a positive relationship was observed between fat intake and

animal product intake rates, suggesting that regions with higher fat supply experienced higher intake of animal products. Animal products and vegetal products are highly negatively correlated so the animal product column was removed to avoid multicollinearity. Below the heatmap figure explores the feature correlation in the caloric intake dataset:

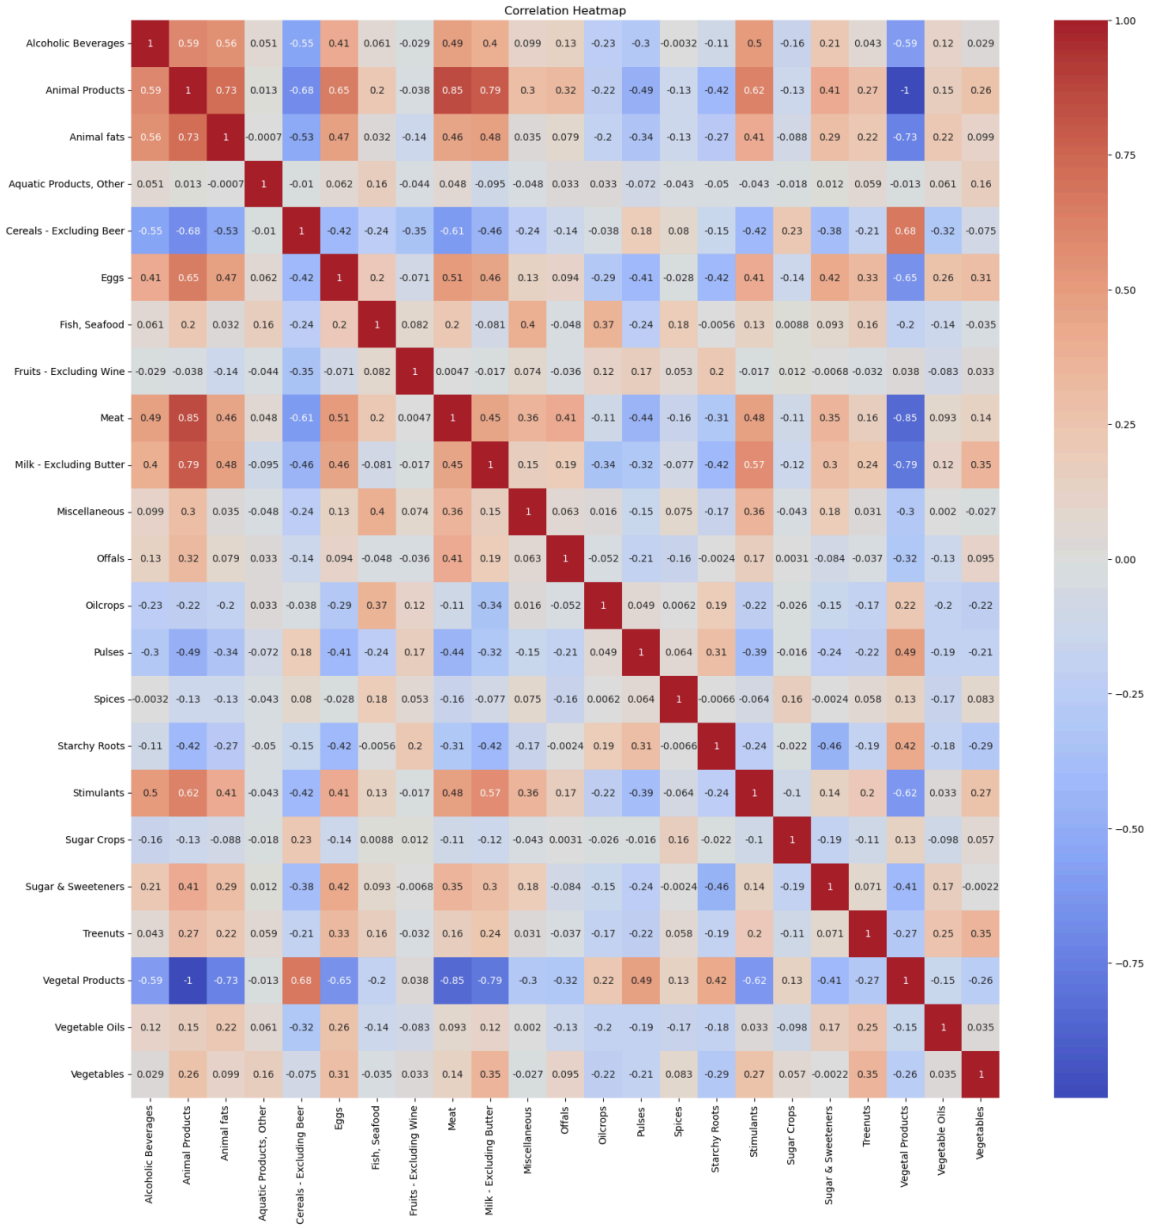

Figure 2. Heatmap of feature correlation in caloric intake dataset

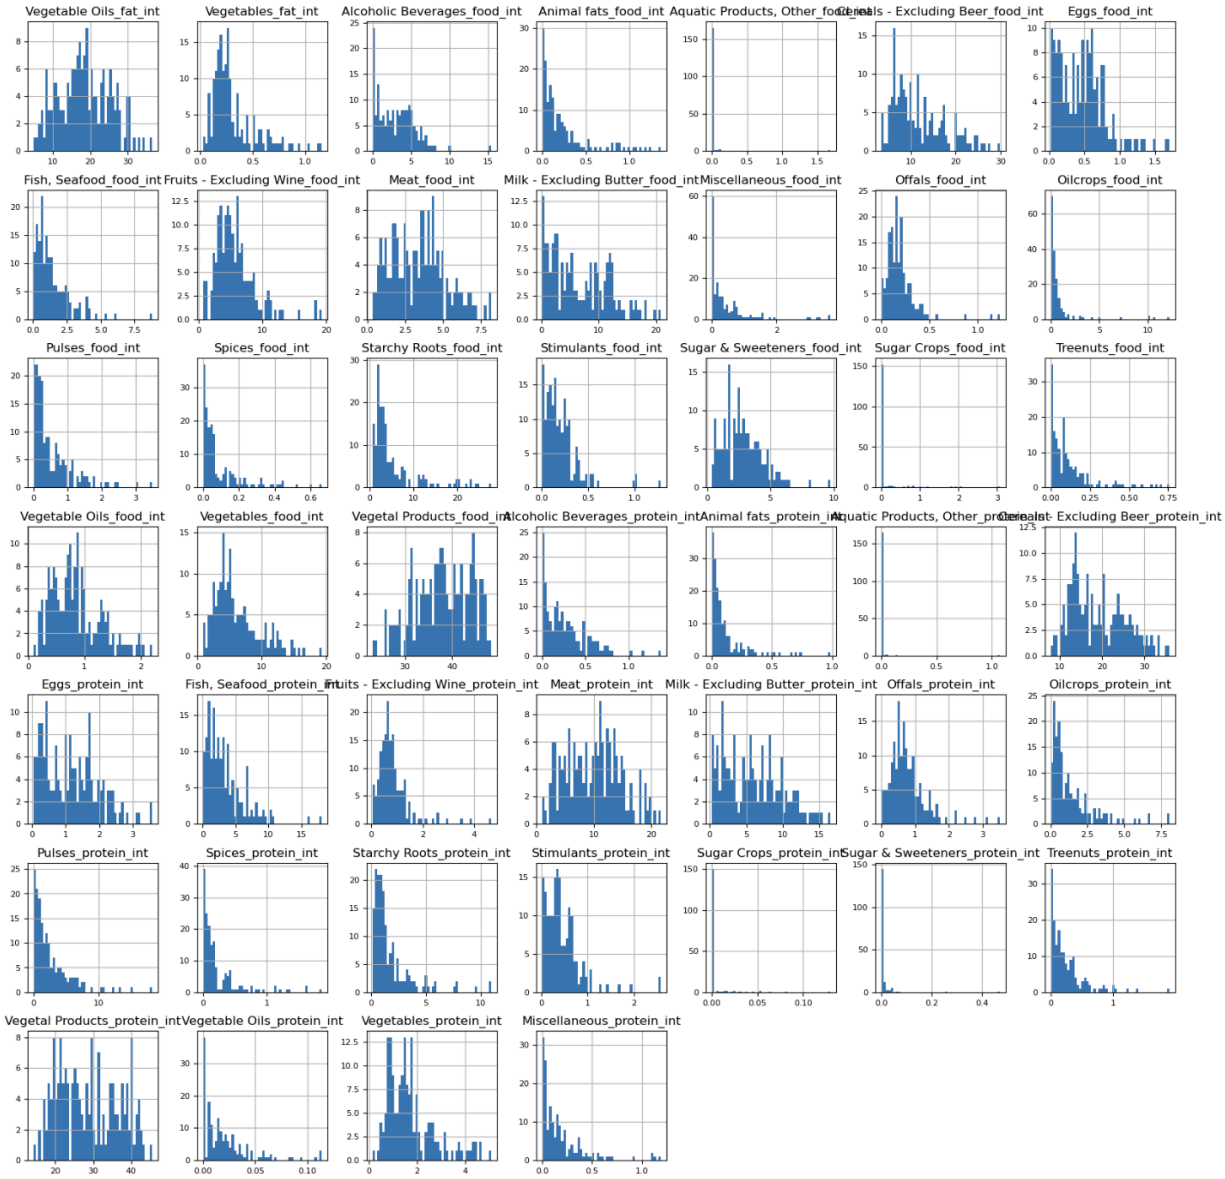
In a different heatmap, alcoholic beverages, animal products (later removed), animal fats, and meat have a positive correlation with COVID deaths. These relationships underscore the importance of nutrient availability in mitigating the severity of health crises. Countries with caloric supply exceeding 2500 kcal/day consistently demonstrated higher recovery rates compared to those with lower caloric intake, highlighting the role of adequate caloric intake in supporting recovery.

The figures below paint the distribution of the numerical features:



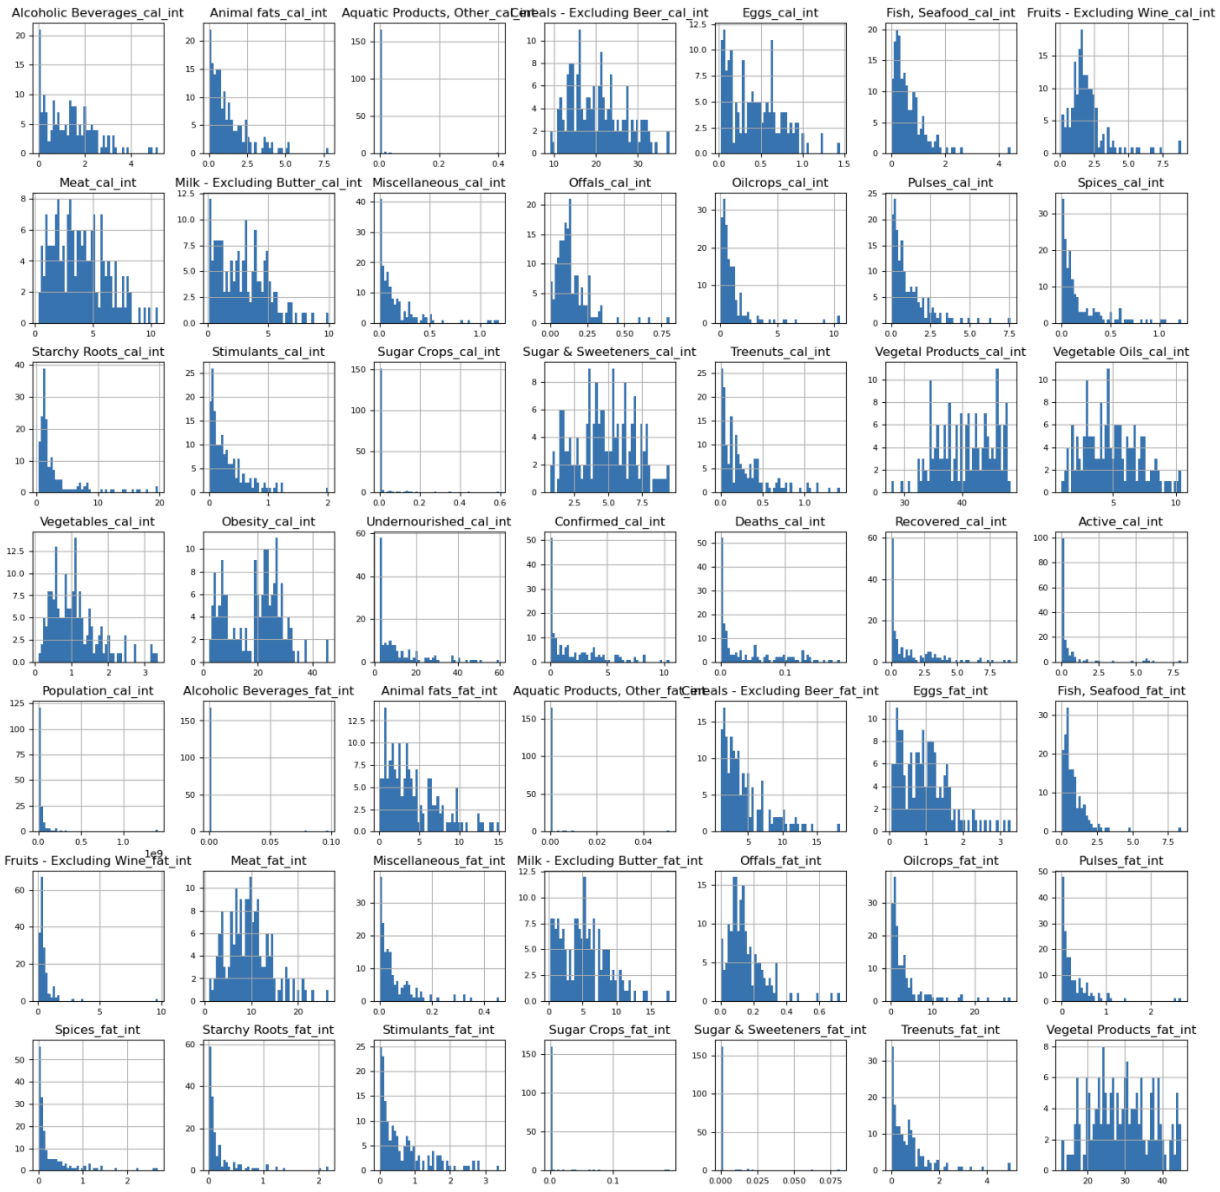


Figure 3. Distribution of the numerical features

High-income countries consistently displayed surplus dietary resources, while low-income countries exhibited critical deficits in protein and caloric supply. This visualization technique effectively highlighted the uneven global distribution of nutritional resources and its potential impact on health outcomes. The EDA findings underscored global nutritional disparities and their significant implications for public health. Higher dietary resources in affluent countries correlate with better COVID-19 outcomes, while deficits in low-income

regions exacerbate vulnerabilities. These insights provide a strong foundation for predictive modeling and policy recommendations, emphasizing the critical role of nutrition in health resilience. Kiribati and Samoa and their obesity rates suffered due to the introduction of western food products. Next to both of these (since they both have a smaller relative population of under 1 million population), the USA has the next highest obesity rate.

Feature Selection and Engineering

Dimensionality reduction and feature selection techniques were critical steps in refining the dataset to enhance predictive modeling.

Recursive Feature Elimination Cross Validation (RFECV) was used to systematically identify the most predictive variables for modeling. The reason for doing 10-fold cross-validation is particularly effective for smaller datasets due to its ability to maximize the use of available data and provide a more reliable estimate of model performance. By dividing the dataset into 10 folds, each fold is used as a validation set once, and the remaining 9 folds are used for training. This allows the model to be trained and evaluated on different subsets of the data, reducing the risk of overfitting. Additionally, with a larger number of folds, the variance in the model's performance across different folds is likely to be smaller, leading to a more stable and reliable estimate. In contrast, fewer folds, like 5-fold cross-validation, might not provide as robust an estimate of model performance, especially with smaller datasets. With fewer folds, each fold contains a larger portion of the data, which can lead to higher variance in the model's performance across different folds.

Protein supply, fat supply, and caloric intake consistently emerged as the top predictors of COVID-19 outcomes, highlighting their strong influence on recovery and mortality rates. Paired with a Random Forest model as the estimator, was employed to rank the features by importance.

The feature rankings were then validated by examining the model's performance metrics, ensuring that the selected features contributed meaningfully to the predictions. In terms of linear importance, the figure below shows the features that have a significant impact on linear regression model:

Feature: 45 Sugar Crops_fat_int, Score: 7.75556
Feature: 47 Treenuts_fat_int, Score: -4.21844
Feature: 50 Vegetables_fat_int, Score: -10.37562
Feature: 52 Animal fats_food_int, Score: -6.30815
Feature: 53 Aquatic Products, Other_food_int, Score: -5.60801
Feature: 54 Cereals - Excluding Beer_food_int, Score: -8.90798
Feature: 55 Eggs_food_int, Score: -25.23133
Feature: 61 Offals_food_int, Score: -9.87039
Feature: 67 Sugar & Sweeteners_food_int, Score: -6.35657
Feature: 68 Sugar Crops_food_int, Score: -19.00679
Feature: 72 Vegetal Products_food_int, Score: -12.99565
Feature: 74 Animal fats_protein_int, Score: -11.50380
Feature: 76 Cereals - Excluding Beer_protein_int, Score: -18.75715
Feature: 77 Eggs_protein_int, Score: -15.70640
Feature: 80 Meat_protein_int, Score: -6.01851
Feature: 87 Stimulants_protein_int, Score: -15.73155
Feature: 88 Sugar Crops_protein_int, Score: -0.05425

Figure 4. Features having a significant impact on linear regression model in terms of linear importance

In addition to these techniques, feature engineering was employed to create new composite metrics that produced deeper insights into the relationship between nutrition and health outcomes. A calorie-to-protein ratio was calculated to address dietary balance, serving as an indicator of the adequacy of protein intake relative to overall caloric consumption. This derived feature captured nuanced dietary diversity indices, which aggregated nutritional metrics to represent overall dietary variety and its potential effect on health outcomes.

These preprocessing steps ensured that the predictive models were trained on the most relevant and informative features, maximizing their power and interpretability. By reducing noise, enhancing feature significance, and incorporating engineered metrics, the modeling

process became more robust and effective. This approach not only improved the models' accuracy but also provided actionable insights into the critical role of nutrition in shaping COVID-19 outcomes, supporting the development of targeted public health interventions.

Data Preprocessing and Cleaning

The first step in preparing the dataset for analysis involved addressing missing values. Missing dietary data for certain countries were imputed using regional averages to maintain consistency while minimizing bias. According to Tan et al. (2019), imputing missing values with region-specific averages is an effective strategy for preserving the statistical integrity of datasets, particularly when regional patterns are known. For example, missing protein intake values for the Sub-Saharan African countries were replaced with the average protein intake of other nations in the region. This method ensured that the imputed values aligned with established regional dietary trends, thereby reducing the risk of introducing systemic bias into the analysis. It was also necessary to convert the string column “Undernourished_cal_int” to a float column during the preparation phase.

“Obesity_cal_int”, “Undernourished_cal_int”, “Confirmed_cal_int”, “Deaths_cal_int”, “Recovered_cal_int”, “Active_cal_int” are all the columns with missing data. To handle this, K-Nearest neighbor was used as a way to fill in missing values in the dataset. The process involves identifying the k-nearest neighbors (k = 5 neighbors) to a data point with a missing value with neighbors determined based on their distance metric Euclidean distance. Once the nearest neighbors are identified, the missing value is imputed using the mean of the corresponding values from these neighbors. One advantage of this approach is that it preserves the underlying patterns in the data and provides more accurate imputations compared to simple imputation of mean or median, improving model performance and insights. Additionally, KNN

Imputer is a non-parametric method, meaning it doesn't make assumptions about the data distribution, making it versatile and suitable for a wide range of datasets.

To standardize the scale of numerical features such as caloric supply, protein intake, and fat intake, normalization was performed using the StandardScaler function from scikit-learn. Normalization is critical in machine learning preprocessing, as it ensures that variables with larger magnitudes do not disproportionately impact the model's performance (Tan et al., 2019). These preprocessing steps transformed the raw dataset into a clean, balanced format, suitable for exploratory data analysis and predictive modeling.

Modeling and Conclusions

Machine learning models - Multiple Linear Regression, OLS Regression, and Random Forest with cross validation, KNN regression, SVM for regression, and XGBoost regressor - were applied to analyze the relationships between dietary metics and COVID-19 outcomes. Of these models, K-nearest neighbors achieved superior robustness and accuracy by aggregating predictions, reducing overfitting and capturing complex nonlinear relationships of nutrition and mortality rates. Model performance was evaluated by maximizing correlation coefficient (R^2) and reducing mean square error. On a performance standpoint, KNN has the highest R^2 (0.44) and lowest MSE. The support vector machine for regression was the next closest predictor with R^2 (0.43).

The present research, therefore, identifies that nutrition became an integral part of COVID-19 outcomes' forecast, particularly mortality and recovery rate in several parts of the world. Among other findings, the most significant evidence was regions with low fat supply had an enhanced probability of death. These all hint at the strong impact of enough nutritional resources as a propeller of resilience in pandemic health situations. The team followed through

with extensive data preprocessing, handling missing values and outliers for dependability in model performance. EDA highlighted some very critical global nutritional inequities, showing that high-income nations had more dietary resources and better health outcomes. Dimensionality reduction and feature selection methods like RFE increased the efficiency of the whole predictive modeling process by enhancing both accuracy and interpretability.

K-Nearest Neighbor was the best, with an correlation coefficient of 0.44, proving its capability to handle complex nonlinear interactions. Feature importance analysis confirmed protein supply to be the most relevant among the selected predictors of the recovery rates. Although KNN, boasts the highest R^2 of the machine learning models that trained, the SVM with a suitable kernel (e.g., RBF) is better at regression due to its scalability and robust algorithm. KNN is better at predicting local relationships with smaller datasets. In contrast, SVM has a more powerful algorithm at predicting high dimensional data and can be further improved upon in the future with the addition of more features and widely available data. It can handle complex relationships, is less prone to overfitting, and can be more efficient than KNN, especially when dealing with large datasets. Experimentation and careful tuning of hyperparameters are crucial to achieve the best results.

The findings have key implications for public health policy. Introducing dietary considerations into global health policy can enhance resilience at the population level to pandemics and other health emergencies. Dietary disparities, especially within low-income communities, become all the more imperative to redress if health inequities are to be reduced and pandemic preparedness improved. Alcoholic beverages, animal products, animal fats, and meat have a positive correlation with COVID deaths.

Animal products and vegetal products are highly negatively correlated so we should remove one (we chose animal products) to avoid mulitcolinearity.
